Conservation importance of Nakai-Nam Theun National Protected Area, Laos, for small carnivores based on camera trap data

Coudrat CNZ1*, Nanthavong C2, Sayavong S2, Johnson A3, Johnston JB4 & Robichaud WG5

Abstract. Laos supports at least 21 species of small carnivores (Viverridae, Prionodontidae, Mustelidae, and Herpestidae) and is considered to be globally important for the conservation of many of these, yet for most species, baseline data on diversity, distribution, conservation, and taxonomic status remain limited. Nakai-Nam Theun National Protected Area (NPA), central-eastern Laos, is ranked among the highest priority of the country's NPAs for national and global biodiversity importance and is one of the largest remaining contiguous forest blocks in Indochina. A wildlife monitoring programme based on camera trap surveys debuted in the area in 2006. From 2006–2011, 10 blocks were sampled covering 900 km² and totalling 20,452 camera trap days. Excluding Felidae, 10 species of small carnivores were photographed during this survey, including the first confirmed record in the wild of Owston's civet Chrotogale owstoni for the area and the second for Laos. This long-term camera-trap programme is one of only two long-term wildlife monitoring programmes in Laos and as such provides some of the most comprehensive data available on small carnivores for the country. The frequency of records for each species, local distribution, and general behaviour observed are presented. Other species known to occur in the area but unrecorded by this camera trap survey are discussed. In total, at least 15 species of small carnivores occur in Nakai Nam Theun NPA. Although small carnivore species may be more resilient to hunting activities than larger mammals, the intensity of hunting with ground snares in the area is likely to result in dramatic population declines if it is not better controlled. Nakai-Nam Theun NPA should be considered as a priority area for the conservation of small carnivores, notably for Vulnerable Owston's civet and its otter species.

Key words. viverrids, prionodontids, mustelids, herpestids, Lao PDR, snare-hunting

INTRODUCTION

More than two decades ago, part of the Indochinese region (namely, 'Northern Vietnam [including adjacent areas in China, Laos, and Thailand]'; Schreiber et al., 1989: 75) was listed as one of the most important areas for the global conservation of small carnivores (mustelids and viverrids). The authors of this report notably recommended increasing research on the distribution, status, and taxonomy of these species, which has generally remained lacking in the region. Within Laos, up until now, the diversity, distribution, and status of small carnivores (here defined as viverrids, prionodontids, mustelids, and herpestids) remain little known. Countrywide wildlife surveys conducted in the 1990s

© National University of Singapore ISSN 2345-7600 (electronic) | ISSN 0217-2445 (print)

provided preliminary information on the group (Duckworth, 1997; Duckworth et al., 1999), although survey intensity and methodology were unlikely to record all species possibly present at any given site visited (Duckworth, 1997). At least 21 species are currently known to occur across Laos (Table 1), including five Globally Threatened and three Near Threatened species (IUCN, 2012). The paucity of data on small carnivores makes it difficult to update their conservation status. However, over the past decade, camera traps were used in some national protected areas (Johnson & Johnston, 2007; Dersu, 2008; Johnson et al., 2009; Duckworth et al., 2010; WCS Lao Programme, unpublished data) and have been proven effective to provide baseline data on many ground-dwelling species. The publication of such longterm data provides invaluable information to increase our understanding of the geographical and ecological distribution of these species and insights into their general behaviour.

Nakai-Nam Theun National Protected Area (NNT NPA), central eastern Laos, has been ranked among the highest priority of the country's NPAs for national as well as global biodiversity importance based notably on species richness, distinctiveness, and endemism (Robichaud et al., 2001), and still remains one of the largest blocks of contiguous forest in mainland Southeast Asia. However, it supports the high levels of hunting typical of much of Laos and Vietnam. To assess the impact of NPA management—primarily law enforcement—on the conservation of the area's terrestrial

mammals, a long-term wildlife monitoring programme using camera traps was initiated in 2006 in NNT NPA, implemented by the Nam Theun 2 Watershed Management and Protection Authority (WMPA), with technical supervision by the Lao Program of the Wildlife Conservation Society (WCS; Johnson et al., 2005; Johnson & Johnston, 2007). We present for the first time results of this survey for small carnivores (excluding small cats) for the period 2006–2011.

MATERIAL AND METHODS

Study area. Nakai-Nam Theun National Protected Area (NNT NPA; Fig. 1) covers ca. 4,000 km² (including recent extensions) with altitudes ranging from ca. 500 to >2200 m asl (above sea level). Around 80% of the NPA remains forested (Robichaud et al., 2009). The NPA is dominated by old growth, largely undisturbed, dry-evergreen forest, with other localised habitat including pine, semi-evergreen, uppermontane and wet-evergreen forest (Timmins & Evans, 1996). Thirty-one villages are located within the NPA; each village is allocated subsistence-use forest areas where villagers are allowed to collect non-timber forest products, including

some common wildlife species according the Wildlife and Aquatic Law and the Forestry Law (National Assembly Lao PDR, 2007a, 2007b).

Camera trap data. Camera trap data were obtained from systematic surveys during 2006-2011 conducted in NNT NPA by the Nam Theun 2 Watershed Management and Protection Authority (NT2 WMPA) staff and a technical advisor assigned by WCS. The sampling programme was designed by WCS, which also provided training to NPA staff for the long-term implementation of the programme (Johnson et al., 2005; Johnson & Johnston, 2007). From March 2006–January 2011, camera traps were set in 10 survey blocks (4-109 km² c.f. Table 2; Fig. 1), selected to represent the different habitats within NNT NPA and to monitor the status of ground animal populations as an indicator of the impact of management strategies in place (Johnson & Johnston, 2007). Three to 50 passive infrared film or digital cameras were set in a survey site (one camera per locality), with cameras being ca. 1 km apart. Cameras were positioned on trees at a height of ~45 cm (targeted for large mammals), beside animal trails or small streams, and/

Table 2. Details of camera-trapping survey effort in Nakai-Nam Theun NPA from 2006 to 2011. Abbreviation: CTD, camera trap day.

^a Faulty cameras are excluded; for (9) in 2009, only data from three cameras were available from the database.

^b Determined with a minimum convex polygon around all camera-traps in ArcGIS 9.3.

Note: Elevation for (9) in 2009 and (7) were missing from the database.

or at other arbitrary open understorey locations. No lures or bait were used. Each camera was programmed to operate 24 hours per day and to take photos at 20-second intervals whenever it was automatically triggered by an object passing in front of it. Most of the cameras (96.8%) had a maximum capacity of 36 photos, therefore survey effort ceased when 36 photos had been taken. The remaining cameras were digital with a capacity of >600 photos, which was never exceeded before removal of the camera. Survey effort for each camera was calculated from the day the camera was set to the day of the last photo taken (for the 36 photos capacity-cameras), or the day of camera removal (for the >600 photos capacity-cameras). Total survey effort (in camera trap days, CTD) is the sum of days cameras were operating, for all cameras. Data from faulty cameras (i.e., cameras for which only the first test-photo was taken, and was found not to be working when collected) were excluded from analysis, as it was not possible to quantify their camera trap days. For each camera, available data included GPS coordinates of location (datum UTM, Indian Thailand), elevation (m asl taken with Garmin GPS60 or Garmin 12 units) and the date and time of each photo.

Of all photos analysed (n = 9,265) during the survey period, small carnivore (excluding Felidae) photo records were identified with the assistance of J. W. Duckworth. To derive the number of photograph records for each species and reduce the risk of double counting, only 'independent photos' were included, defined here as consecutive photographs of individuals/social units of the same species taken more than 30 minutes apart (except when the same individual/social unit could be identified and was photographed consecutively for over 30 minutes) and non-consecutive photos of individuals/ social units of the same species (following O'Brien et al., 2003). Camera trap localities and record details for each camera-locality are presented. We also present the relative encounter rate (i.e., total independent photos of small carnivore species/total camera trap days for the period*100) of carnivore species and survey effort (i.e., camera trap days)

pulled per month. Additional records of small carnivore species from incidental observations during foot surveys conducted by CNZC and CN in 2011–2012 are tabulated.

RESULTS

Ten blocks were sampled (Fig. 1) over the survey period, totalling 20,452 camera trap days (Table 2). Ten small carnivore species ('species' sensu lato – ferret badger species

Table 3. Number of independent images taken for each species over the 20,452 camera-trap days period, elevation and percentage of them taken at dusk (1700–1900 hours), night (1900–0500 hours), dawn (0500–0700 hours), and in day time (0700–1700 hours). Note: Dusk and dawn may vary across seasons in the area.

^a Number of camera-trap-locality (a single camera-trap per locality) where recorded, out of the 469 camera-trap-sites set.

are not identifiable from images and therefore considered as *Melogale* sp(p).) were photographed (Table 3). Ferret badger sp(p). were the most frequently recorded (101 independent photos), followed by common palm civet (100), hog badger (80), large Indian civet (79), Owston's civet (60), masked palm civet (55), crab-eating mongoose (40), yellow-throated marten (18), spotted linsang (5), and binturong (1).

The elevation range at which each species was recorded (Table 3) fell into the documented range in Laos (Duckworth et al., 1999; Johnson et al., 2009; Sivilay et al., 2011).

The 24-hour activity cycle varied between species. Yellowthroated marten and crab-eating mongoose were largely recorded from dawn through day time (0500–1700 hours); whereas the other eight species were predominantly recorded from dusk through night time (1700–0500 hours). Spotted linsang, yellow-throated marten, hog badger, and crabeating mongoose were the most regularly recorded at dawn (0500–0700 hours; >10% of images; Table 3).

The months of April, December, January, March and November received the maximum survey effort (in camera trap days: 4010, 3749, 2764, 2820, and 2515 respectively; Fig. 2). Relative encounter rates for all species combined (i.e., total independent photos of small carnivore species/total camera trap day for the month) were expectedly the lowest during the poorly surveyed months of the wet season (June-September). However, despite high survey effort in January and December, relative encounter rate was relatively low during both months (0.4 and 0.7 respectively). Conversely, although the months of October and May were surveyed less (585 and 1407 camera trap-days respectively), the relative encounter rate for these two months were among the highest (1.9 and 1.6 respectively). Overall, relative encounter rates were the highest for the months of March (3.0), April (1.9), October (1.9), and May (1.6; Fig. 2). Pulled by seasons, the relative encounter rate was the lowest during the cold-dry season (November-February; 0.69), followed by the warmwet season (April-September; 1.48) and highest for the two

intermediate months (March and November; 2.79). Other factors may however influence these results such as habitat type and hunting pressure.

Distribution of records was not uniform across the areas sampled between the different species (Figs. 3, 4; Appendix). Common palm civet was the only species recorded at all 10 survey blocks and was recorded from the highest number of camera trap localities (n=52). Encounter rate and localities were the fewest for spotted linsang and binturong.

Large Indian civet, masked palm civet, Owston's civet, crab-eating mongoose and yellow-throated marten were photographed one (large Indian civet) to four times (crabeating mongoose) with conspecifics (two to three animals). Only crab-eating mongoose was recorded in groups of over two individuals (Table 4; Appendix 3).

During survey work in 2011–2012, additional records for six species (five of which recorded from the camera trap surveys) were documented from incidental observations in the wild or from hunter camps or snare traps (Table 5; Appendix 1).

DISCUSSION

During a five-year camera trap programme in the NNT NPA, 10 species of small carnivores were recorded of which two are classified by the IUCN Red List of Threatened Species as Globally Threatened (Vulnerable) and two as Near Threatened (IUCN, 2012; Table 1). Nine species had previously been confirmed in the area (Duckworth, 1997; Duckworth et al., 1999; Robichaud & Stuart, 1999; Robichaud, 2010). Of the small carnivores captured on camera the Owston's civet is the first confirmed field record for the NPA (Johnson & Johnston, 2007), and the second for the country (Johnson et al., 2009; see below).

In 1994 and 1996, 10 small carnivore species were directly observed within one part of NNT NPA (Duckworth, 1998), of which three were not recorded from this study (Siberian

Table 4. Details of photographs that captured groups (≥2 individuals) of animals (c.f. Appendix 3).

Fig. 2. Total survey effort (in camera trap days) per month over the 2006–2011 survey period (bars) and relative species encounter rate (i.e., total independent photos of small carnivore spp./total camera trap day for the month). Relative encounter rates were highest during the warmest and well-surveyed months—peaks are observed in March (start of the warm season) and October (still within the warm season). Despite high survey effort in January and December (cold season), encounter rates were low.

weasel, stripe-backed weasel, small-toothed palm civet; see below). This highlights, in part, the differing adequacy of methodologies and survey designs for recording some species. Indeed, the characteristics of the camera trapping methodology, here focusing on a broad range of larger and ground-dwelling mammals or large birds rather than being species-specific means that results do not present the comprehensive species diversity occurring in NNT NPA. For instance, weasels, otters, and arboreal species were unlikely to be recorded in this survey design due to their characteristic habitat use (dense undergrowth; along large rivers; up in the canopy, respectively), not well (or at all) represented by the locations of cameras. In Nam-Et Phou Louey NPA, northern Laos, 10 species were also recorded during a longterm camera trap survey (8,499 camera trap days) of which eight are in common with NNT NPA (Johnson et al., 2009). Compared to other Southeast Asian countries, the number

of species recorded by camera traps in NNT NPA falls in the upper range (5–12) of small carnivore species richness (excluding cats and otters) recorded from intensive camera trap surveys (>1,000 camera trap days) at single sites (e.g., Grassman, 2003; Kawanishi & Sunquist, 2004; Than Zaw et al., 2008; Holden & Neang, 2009; Chen et al., 2009; Cheyne et al., 2010; Wilting et al., 2010; Jenks et al., 2011).

When deploying camera traps, taking into consideration the respective ecology and behaviour of small carnivore species can increase detectability. For instance, placing additional cameras in trees or other microhabitats may record species that are semi- or mainly arboreal or strongly associated with specific microhabitat features. In addition, using baits at camera locations and/or increasing survey effort during seasons when species activity increases are likely to result in higher encounter rates (Sollmann et al., 2013). Our study

Fig. 3. Distribution of camera-trap records for Viverridae and linsang in Nakai-Nam Theun NPA from 2006–2011.

shows that species encounter rate may be, in part, influenced by season in NNT NPA, with a catch rate highest during the warm season, when animals tend to increase their activity levels, as had been previously suggested (Duckworth, 1997). However, other factors may also influence the differing encounter rates between sampling blocks, such as habitat type and hunting pressure. In highly heterogeneous habitats such as NNT NPA, species records and encounter rates at any one site are unlikely to be representative of the presence/ absence of each species or of their relative abundance due to the inconstant detection probability across time, space, and species (Sollmann et al., 2013). Sampling design (e.g., camera set-up, camera model, sample size) and species' behavioural ecology (e.g., home range, habitat use), which in turn can vary across space and time, influence encounter rates in camera trap studies (Sollmann et al., 2013), which prevents drawing any conclusions on species abundance between survey sites in this study. Our camera trap survey was not initially intended as an estimate of species abundance between sampling blocks, but rather to use the data to evaluate change in occupancy of terrestrial mammals within a sampling block over time as a result of the NPA management (largely zoning and law enforcement; Johnson et al., 2005).

Viverridae. Five civet species were photographed in NNT NPA (Table 3) including Owston's civet, the first confirmed field record for the NPA. The common palm civet and large Indian civet were the most widely recorded species and found over the largest altitudinal ranges, which concurs with sighting records of the two species across Laos (Duckworth,

1997) and another camera trap survey in northern Laos (Johnson et al., 2009). The distribution of records for the other three civet species was more restricted, which may reflect their affinity to higher elevations within NNT NPA. Masked palm civet is considered to range only above 500 m asl in Laos (Duckworth, 1997; Duckworth et al., 1999). There were few or no records of masked palm civet from sampling areas at lower elevations (Table 3). It is possible the species' semi-arboreality may render its camera capture under-represented. In Myanmar, in some areas where captive or dead specimens of masked palm civets were often recorded, relatively high camera trap efforts (~300–2,000 camera trap-days) failed to record images of this species (Than Zaw et al., 2008).

Little is known about the distribution and status of Owston's civet across its range; it is only known from China, Vietnam, and Laos (Roberton et al., 2008). Our records in NNT NPA (17°47'N to 18°19'N) fall within the range of the known distribution. Additional records in the wild from Laos come from only two other locations (Nam-Et Phou Louey NPA, northeastern Laos, ~20°N: Johnson et al., 2009 and Phou Chomvoy Provincial Protected Area, central eastern Laos, 18°29'N: Sivilay et al., 2011) at elevations >1,000 m asl. The species is yet to be confirmed south of NNT NPA in Laos but the current southernmost record in Vietnam (12°21'N; Dang & Le, 2010) would suggest the species also occurring in southern Laos in suitable habitat. The species has never been recorded in Cambodia, but it is believed that if present, it would only have a restricted range in the northeast within suitable habitat and climatic conditions (Holden & Neang, 2009). Across its range, the species has been recorded via camera traps from elevations of 400 to ca. 1,700 m asl (Rozhnov et al., 1992; Grieser Johns, 2000; Johnson et al., 2009; Dang & Le, 2010; Sivilay et al., 2011). The species

in Laos may however be restricted to the upper elevation range. Records from the Vietnamese side of the Annamite Mountains go below the lowest altitude of NNT NPA, e.g., in nearby Pu Mat Nature Reserve, Vietnam, Grieser Johns (2000) camera trapped it down to 400 m. However, habitat is significantly different between the two aspects of the Annamite Mountains, notably in terms of dry-season: this is benign in the east (Vietnam side) but long and harsh in most of the west (Timmins & Trinh, 2001), and this may explain the differing altitudinal distribution of the species between the two sides.

The single record of binturong during this survey may in principle be due to arboreality, rarity, and/or the positioning of cameras. One individual was observed and filmed in daylight in the canopy during a visit around Phou Vang survey block in March 2011 (Robichaud, W.G. pers. data). This species is mainly arboreal but regularly comes to the ground when it cannot cross the canopy (Widmann et al., 2008). Elsewhere in Asia, camera trap surveys at sites where binturongs occur captured few or no photographs of the species (e.g., Datta et al., 2008; Than Zaw et al., 2008; Holden & Neang, 2009; Cheyne et al., 2010; Wilting et al., 2010; Jenks et al., 2011; Samejima & Semiadi, 2012).

Virtually all known Asian civets are nocturnal (Jennings & Veron, 2009), and this was reflected in our study results. All civet photographs were recorded between 1731–0543 hours, with 91% of photographs during night time (1900–0500 hours). Sociality of these species is poorly known; they are all classified as solitary but occasionally are found with conspecifics, as shown in a few photographs in this study with duos of adult-size individuals of masked palm civet, large Indian civet, and Owston's civet, all taken during March–May (Table 4). This is the end of the dry season in Laos, and

the concentration of the photographs suggests it possibly coincides with the mating season, although it is unclear from the images of what age and sex the individuals were. During foot surveys in Laos, groups (2-5 individuals) of masked palm civet and common palm civet were occasionally sighted (Duckworth, 1997; Johnson et al., 2009), and in Cambodia, 2-5 common palm civets were regularly photographed at a salt lick (Edwards, 2012). Our single image of a pair of large Indian civets where the individuals are sniffing each other's perineal region, may indicate they are engaging in mating behaviour. In Cambodia, in May 2011, a pair of Viverra/Viverricula (species unconfirmed) was observed in trees ~ 10 m above ground; the authors speculated that the animals were possibly involved in a reproductive behaviour, as these species are almost always observed to be solitary and on the ground (Iseborn et al., 2012). The species has been reported to breed throughout the year (Lekagul & McNeely, 1988), although this has never been studied in wild populations. Similarly, little is known of the breeding seasons of masked palm civet and Owston's civet in the wild. Common palm civet was not photographed in pairs/ group in this study. This species has been sighted copulating in the wild (though near human settlement) in March and September (Borah & Deka, 2011).

Prionodontidae. Four photos were taken of the spotted linsang. This low frequency of photo-capture of linsang Prionodon spp. is common during camera trap surveys across their range, when the species is not targeted (e.g., Datta et al., 2008; Than Zaw et al., 2008; Holden & Neang, 2009; Cheyne et al., 2010; Wilting et al., 2010; Jenks et al., 2011). Camera traps generally exclude postulated preferred micro-habitats of the species; as an ambush hunter, it may spend most of its ground-level time hidden in thick understory vegetation (J. W. Duckworth, pers. comm.) where camera traps are rarely set. Linsangs are semi-arboreal species, possibly primarily ranging in dense understory from one metre above the ground to above canopy (Kuznetzov & Baranauskas, 1993; Van Rompaey, 1995). The species remains poorly known but it has been found in various forest types and over a wide altitudinal range where it occurs and seems resilient to degraded habitat (Roberton et al., 2008). The species seems mainly active at dusk and night (e.g., Johnson et al., 2009; Redford et al., 2011; Baker et al., 2012; Ghose et al., 2012) but has been sighted active in the wild during daytime in Assam, India (Borah, 2010).

Mustellidae. Four mustelid taxa were camera trapped. Unidentified ferret badgers were the most frequently camera trapped taxa, although they were not evenly recorded throughout the sampled areas. The distribution of *Melogale* spp. in Laos and neighbouring countries remain uncertain. Two species of ferret badgers have been recorded in Laos: large-toothed *M. personata* and small-toothed *M. moschata* ferret badgers (Duckworth et al., 1999), and a third, *M. cucphuongensis*, has recently been named from neighbouring Vietnam (Nadler et al., 2011), and could plausibly inhabit Laos (if valid taxonomically). Despite intensive camera trap survey in Nam Et-Phou Louey NPA, northeastern Laos, no images were taken of the genus (Johnson et al., 2009), suggesting the possibility of this being a true reflection of their status in the area, given the comparatively high frequency at which it was recorded in NNT NPA. However, other factors such as differences in camera positioning might also contribute to this pattern.

On current knowledge, species identification requires observation of the skull and dentition (Schank et al., 2009; Robichaud, 2010), therefore few records across Laos have been identified to species. Both *M. moschata* and *M. personata* have been confirmed to occur in NNT NPA from records of one skull for each species found in a snare and a poacher camp, respectively (*M. moschata*: Robichaud, 2010; *M. personata*: Coudrat & Nanthavong, 2013). Our photographs of the genus in NNT NPA show variation in the individuals' fur colouration, from light brown to grey (see Appendix 2). This variation may be found within single species (e.g., Schank et al., 2009; Nadler et al., 2011) as is also observed in other small carnivore species (Veron et al., 2004). Photographs corroborate the genus as nocturnal in NNT NPA.

Hog badger was recorded widely in terms of altitude, geography, and photo-capture frequency. Records (and field observations from NNT NPA) suggest the species can be active during day and night time, as has previously been found in Myanmar (Than Zaw et al., 2008).

Activity cycle, altitudinal range, and sociality of yellowthroated marten recorded from this survey is consistent with previous studies, in which the species has been recorded primarily by day and often travellings in small groups (e.g., Duckworth, 1997; Parr & Duckworth, 2007; Datta et al., 2008; Holden & Neang, 2009).

Herpestidae. The photos of crab-eating mongoose in duos or groups of 3–4 individuals are consistent with previous observations that this species regularly travel with conspecifics (Duckworth, 1997; Than Zaw et al., 2008; Johnson et al., 2009). The species was primarily recorded from 0500–1700 hours, consistent with previous records across its range, where no pictures/sightings have been made later than 1830 hours and earlier than 0430 hours (e.g., Duckworth, 1997; Than Zaw et al., 2009; Holden & Neang, 2009; Edwards, 2012).

Other species not recorded during the camera trapping. Five species previously documented in NNT NPA (Timmins & Evans, 1996; Duckworth, 1997; Dersu, 2008) were not recorded in this study. Both the stripe-backed weasel *Mustela strigidorsa* and the Siberian weasel *M. sibirica* have been sighted at least once in NNT NPA (Duckworth, 1997; Duckworth, 1998; Abramov et al., 2008; Streicher et al., 2010; Coudrat CNZ, pers. obs., 2014). Little is known of their ecology and habitat use. On 31 January 2014, 6:46 am, the first author (CNZC) observed an individual of *M. strigidorsa* at 17°51'55.36"N 105°15'16.00"E, 969 m a.s.l. during a visit in NNT NPA. The animal came a metre away from the observer and was foraging on the ground in thick vegetation, in dry evergreen forest. Both species have been recorded in various habitat types across their range; however, stripe-backed weasel probably occurs mainly in hill and mountain regions with forest towards the evergreen end of the forest spectrum for which NNT NPA is typical; but the regional habitat use of Siberian weasel remains poorly understood (Lekagul & McNeely, 1988; Duckworth et al., 1999; Abramov et al., 2008).

The small-toothed palm civet *Arctogalidia trivirgata* is at least locally common in NNT NPA (Duckworth, 1997), but is a strictly arboreal species (Duckworth & Nettelbeck, 2007), which explains its absence from image records from ground-level camera trapping.

At least two otter species have been previously reported from the area: Oriental small-clawed otter Aonyx cinereus and a larger unidentified otter species (see Timmins & Evans, 1996; Duckworth, 1997; Dersu, 2008). Otters were not recorded during our study, as no camera traps were positioned along large riverbanks. Tracks of otters were commonly observed along large rivers in the area in 1996 (Timmins & Evans, 1996), and surveys in the lowland (<500 m asl) western part of the NPA (referred to as Nakai plateau) in 2006-2008 recorded at least two species of otter (largely on the basis of signs) in association with most river stretches surveyed (Dersu, 2008), and several tracks (unidentified species) were observed along the Nam Theun in 2012 (Coudrat, 2012). Future camera trap surveys in NNT NPA should focus on the identification of otter species occurring in the area and be positioned along large rivers.

Various small carnivores known from Laos remain unrecorded from NNT NPA except from the Nakai plateau, part of which has, since 2008 (Illangovan, 2011), been inundated by the reservoir from the hydroelectric dam Nam Theun 2. Two of these species are tied in Laos to highly deciduous and/or degraded habitats: small Indian civet, Viverricula indica; and small Asian mongoose Herpestes javanicus (see Duckworth et al., 1999; Dersu, 2008; Duckworth et al., 2010). For these, there is presently little, if any, suitable habitat in the NPA. Large-spotted civet probably occurs, or used to, on the Nakai plateau (Khounboline, 2005), but this seems to be about its upper altitudinal limit in Laos (Duckworth et al.,1999) and it is likely to be extremely local, if present at all, in the NPA. The yellow-bellied weasel Mustela kathiah, not recorded from the NPA, is known to inhabit highlands (over 1,000 m) both north and south Laos (Tizard, 2002; Duckworth & Robichaud, 2005) and presumably occurs along the intervening Annamite spine, although there are as yet no records. Like other weasels in Southeast Asia, it seems to be poorly recorded by camera traps (Supparatvikorn et al., 2012), so it may well inhabit NNT NPA. Two other species have not been confirmed in the NPA, but are so difficult to identify that they may have been detected but not identified: smooth-coated otter and Eurasian otter.

Threats. In Laos, of all small carnivore species discussed here, civets are the most commonly found sold in markets as food, processed products for traditional medicine, trophies or pets, and are also traded with Vietnam (Duckworth et al.,

1999; Nooren & Claridge, 2001). In NNT NPA, the extent of small carnivore hunting-whether for local consumption or trade with Vietnamese-is unknown. However the large number of snares set by Lao and Vietnamese poachers in the protected area (Robichaud et al., 2009; Coudrat, 2012) undoubtedly catch voluminous amount of these animals, targeted or not. Some villagers in NNT NPA have reported that civet meat is favoured, while meat from yellow-throated marten, badger species and weasels is disliked (WMPA, unpublished data). Interviews of rural households in Lao uplands in the north and south of Laos have revealed that wild meat, including several small carnivore species, traditionally formed a large part of upland Lao people's diet, but unsustainable harvest has led to the decrease of these species' wild populations (Krahn, 2005; Krahn & Johnson, 2007). From these interviews, it was found that annual kill rates of viverrid species have dramatically decreased (Krahn, 2005) with a switch to smaller-bodied animals (such as squirrels and rats) now reportedly more commonly hunted (Krahn & Johnson, 2007). The intensity of snare hunting in the area put these species at high risk of critical population decrease in the future. Small carnivores species, however, may be relatively resilient to hunting compared to larger mammals. In adjacent forest areas in Vietnam where hunting is much more intense and forest blocks more fragmented, small carnivores are still found at relatively high numbers (e.g., Timmins & Trinh, 2001). In comparison, the huntingsensitive wild cats have already been dramatically reduced in NNT NPA from snares hunting (Coudrat et al., in press).

Overall, 15 species of the 21 species confirmed to occur in Laos are found in NNT NPA. As small carnivore species remain very poorly known, a wide variety of new techniques for placement of cameras should be considered in future camera trap that are intended for species identification. NNT NPA is one of the largest remaining forest blocks in Indochina, and as such is still one of the most important for the conservation of small carnivore species, notably for Vulnerable Owston's civet (Schreiber et al., 1989), and at a regional level also is very significant for its two/three species of otters (Dersu, 2008).

ACKNOWLEDGEMENTS

We sincerely thank NT2 WMPA for permission to analyse their camera trap data. The camera trap programme was implemented by NT2 WMPA staff from 2006-2011. The programme was designed by the Wildlife Conservation Society-Lao programme in 2005, and who also trained the WMPA staff for programme implementation and coordinated the programme from 2005-2007. Particular thanks are given to Phouthone Sophathilath, Soukhatha Vannalath, and Chanthavy Vongkhamheng of the WMPA. Villagers from Nakai-Nam Theun NPA assisted during camera trap surveys. Foot surveys in 2011–2012 presented in this paper were part of CNZC's PhD research and permission was obtained from the Government of Lao PDR, in particular from the Department of Agriculture and Forestry. Robert Timmins and Dr. Stephen Ling both assisted WCS for species identification of the camera trap photographs database and

J. W. Duckworth verified the identification of species from the photographs in this study. We thank J. W. Duckworth, three reviewers, and RBZ's editor for comments, which substantially improved the manuscript.
